Theory and Experiments on the Stability of Robot Compliance Control

Brian J. Waibel and H. Kazerooni, Member, IEEE

Abstract—This work presents a nonlinear stability analysis for constrained robotic motion, a maneuver where the manipulator contacts the environment. The external disturbances, sensor noises, parameter uncertainties, and the dynamics of the total system comprised of the robot and the environment have been modeled. The control of the manipulator is divided into two components: a computed torque trajectory controller that regulates the robot position and a compliance controller that modulates contact forces. Three sufficient conditions for stability have been derived. The first condition guarantees the stability of the system of robot and finite stiff environment when no force sensor and, consequently, no force feedback is considered for the system. The second condition guarantees stability of the robot and environment when a compliance compensator (operating on the contact force) supplements the trajectory controller. For a fixed trajectory controller, this criterion shows that the $L_2$ gain of the compliance controller must vary in inverse proportion to the environment stiffness in order to guarantee stability. This criterion also shows that stability of the compliance compensator cannot be guaranteed when the robot operates near a singular point. The third stability criterion shows that, for a robot contacting a very stiff environment, the gain of the compliance compensator must vary in inverse proportion to the gain of the trajectory compensator.

NOMENCLATURE

- $\theta_d, \dot{\theta}_d, \ddot{\theta}_d$: Command trajectory, velocity, and acceleration in joint space.
- $n$: Degrees of freedom for manipulator.
- $K(s)$: Laplace transform of trajectory compensator.
- $M, \bar{M}$: Actual and model of the robot inertia matrix.
- $C, \bar{C}$: Actual and model of coriolis, centrifugal, and gravitational forces.
- $\tau_d, N_T$: Torque disturbance and its $L_2$ bound.
- $J(\theta)$: Jacobian matrix.
- $I, 0$: Identity matrix and zero matrix.
- $u$: Forces/torques applied by manipulator's actuators.
- $\theta, \dot{\theta}, \ddot{\theta}$: Joint positions, velocities, and accelerations.
- $p$: System state measurement error vector.
- $q$: Command trajectory comprised of desired joint position and velocity ($\theta_d^T, \dot{\theta}_d^T$).
- $H$: Laplace transform of compliance compensator.
- $e, \phi$: Input signal for and output signal from trajectory compensator.
- $x, \dot{x}$: Position and velocity of manipulator endpoint and of the environment.
- $E$: Environment function mapping environment deflection to contact force.
- $f, m$: Contact force and its measurement noise.
- $A, B$: Matrix coefficients for manipulator's state space linear dynamics.
- $D$: Laplace transform of manipulator's linear dynamics.
- $\Delta C$: Quantity representing modeling error in the coriolis and centrifugal forces.
- $\mu, \xi$: Signal representing the nonlinear and modeling errors of the manipulator dynamics.
- $T, S$: Transfer function matrices derived from the manipulator's linear dynamics.
- $\alpha_T, \alpha_S$: $A$ norm of $T$ and $S$.
- $\alpha_M$: Bound on model for the inertia matrix.
- $\alpha_{M1}, \alpha_{M2}$: Bounds on $M^{-1}$ and $M^{-1}\bar{M} - I$.
- $\alpha_{E1}, \alpha_{E2}, \alpha_E$: Bounds on the environment dynamics.
- $\alpha_{Kin}$: Bounds on the forward kinematics.
- $\alpha_{JT}$: Bounds on the inverse Jacobian.
- $\Delta x, \Delta \dot{x}$: Output from compliance compensator and signal from compliance control loop.
- $\Delta q$: Compliance compensator result which is subtracted from command trajectory.

I. INTRODUCTION

APPLICATION of robotics to manufacturing tasks requires a mechanical interaction with the environment or with the object being handled, in addition to high-speed maneuvering in unconstrained space. For example, in a robotic assembly task whose objective is combining a number of individual parts into one completed device, the parts must be quickly assembled while avoiding damage to either the individual parts or the device. The very nature of the assembly process requires the robot (through the part) to contact the environment (the partially completed device). To successfully complete this constrained maneuver, the manipulator must develop compliant motion where the interaction force along the constrained direction is accommodated rather than resisted.

Whitney [21] identifies six different approaches for robot force control. These six may be divided into two categories of compliant motion development: hybrid control and compliance control. The hybrid control method controls force and position in a nonconflicting way [13]-[16], [18] commanding force along directions constrained by the environment and position along those directions in which the manipulator is unconstrained. The compliance control approach focuses on the relationship between the manipulator position, the commanded quantity, and the interaction force, a specified function of the command signal. With this approach, the designer can ensure that the manipulator will maneuver in a constrained space while maintaining an appropriate contact force.

1 The term "force" implies both forces and torques. Position, in a Cartesian sense, implies both position and orientation.
This work represents a synthesis and extension of the stability analysis of Spong and Vidyasagar [19] and the compliance control analysis in Kazerooni et al. [9]. Spong and Vidyasagar model the dynamics of a robot performing unconstrained manipulation and derive a criterion for closed-loop trajectory control stability in light of parameter uncertainties, external disturbances, and sensor noise. Kazerooni et al. define a compliance controller and derive a nonglobal stability condition for manipulation interaction with an infinitely stiff environment. Other approaches in stability analysis of compliant motion control can be found in [1]–[3], [5], [8].

We are concerned with the global stability of a manipulator interacting with an environment. We apply the analysis of [19] to both the manipulator and environment dynamics and derive global stability conditions for the system taken as a whole. The mathematical conventions and nomenclature of this paper are contained in Appendix A. Section II describes the manipulator dynamic behavior, and Section III models the dynamics behavior of a finite stiffness environment. Section IV analyzes the manipulator interaction with a finite stiffness environment and derives a stability condition from which the stability results of [19] can be obtained as a special case. Section V defines a compliance feedback controller to modulate the interaction with a finite stiffness environment. Section VI differentiates between finite and infinite stiffness environments and, for an infinite stiffness environment, a stability condition analogous to that in Section V.

II. MANIPULATOR DYNAMICS

The dynamic behavior of a direct drive robot with n degrees of freedom can be expressed by

\[ M(\theta)\ddot{\theta} + C(\theta, \dot{\theta}) = u + \tau_d - J^T(\theta) f. \]  

(1)

There are three inputs to the robot dynamics: the actuator torques, \( u \); a disturbance torque \( \tau_d \) and the applied forces \( f \) acting at the endpoint and transformed into joint forces via the Jacobian transpose matrix \( J^T(\theta) \). The Jacobian \( J(\theta) \) is assumed to be a square matrix.\(^3\) The disturbance torque \( \tau_d \) is a function solely dependent on time that encompasses all exogenous inputs. While this might, in many cases, be difficult to model, it is assumed that, for the purposes of stability analysis, the \( L_\infty \) norm of \( \tau_d \) is bounded such that \( \|\tau_d\|_\infty \leq \alpha_{\tau_d} < \infty. \) Notice that if the disturbance torque \( \tau_d \) and the applied force \( f \) are zero, the system may be an unstable function of the actuator torque, i.e., a finite torque may cause the joint positions to grow unboundedly.

Based on the manipulator dynamics of (1), a trajectory controller is chosen to stabilize the nonlinear dynamics of the robot manipulator. This trajectory controller requires some information about the robot’s position \( \theta \) and joint velocities \( \dot{\theta} \). Together, these quantities represent the manipulator’s states, which we denote by the \( 2n \) vector \( q \in [\theta, \dot{\theta}]^T \). \( q \) represents the actual system states, but only the measured states are available for the controller. It is assumed that the measured system states \( q + \rho \), where \( q \) is the actual system states and \( \rho \) represents the \( 2n \) vector of measurement noise. To support the stability analy-

\[^2\] Unless otherwise noted, all matrices are \( n \times n \) and all vectors are \( n \times 1 \). Hereafter, the arguments for all functions will be omitted except when new quantities are defined or when required for clarity.

\[^3\] The solution of differential equation (1) when \( u, f, \tau_d \) are finite is defined as the robot workspace. This implicitly eliminates any point that \( J(\theta) \) is singular.

\[^4\] The symbol \( \hat{\alpha} \) means “is defined as.”

sis, the measurement error \( \rho \) is assumed to be a Lebesque measurable function\(^5\) and its \( L_\infty \) norm is bounded such that \( \|\rho\|_\infty \leq \alpha_\rho < \infty. \)

Using the “computed torque method,” a model-based control scheme, the input torque \( u \) is defined as

\[ u = \hat{M}(\dot{\theta})\ddot{q} + \phi + \hat{C} \]  

(2)

where \( \hat{M} \) and \( \hat{C} \) are the nominal models for \( M \) and \( C \). These models are either derived experimentally or analytically. \( \dot{\theta} \) is the feedforward, joint space command acceleration. \( \phi \) is the output signal from the linear trajectory compensator and is defined as

\[ \phi = K^* (q - \dot{q} - p) \]  

(3)

where \( \phi = K^* (q_e - q - p) \) and \( q_e \) is the convolution of the impulse response of \( K(s) \) with the signal \( q_e \). \( q_e \) is a \( 2n \) vector function for the command position and velocity, and \( K = [K_P \ K_V]; K_P \) and \( K_V \) are, in general, stable transfer function matrices. For a proportional-derivative trajectory controller, \( K_P \) and \( K_V \) are constant, diagonal matrices. \( K \) is an \( L_\infty \)-stable function of its input such that \( K(\cdot): L^\infty_\infty \rightarrow L^\infty_\infty \) and

\[ \|\phi\|_\infty \leq \alpha_K (\|q\|_\infty + \|\dot{q}\|_\infty + \|p\|_\infty) \]  

(4)

where \( \alpha_K \) denotes the \( \hat{A} \) norm of \( K \). (See Appendix A.) Substituting (2) into (1) results in (5) where \( \phi \) represents the output of the robot’s linear trajectory compensator, and a signal \( \mu \) represents the output of all the nonlinear and feedforward dynamics.

\[ \ddot{\theta} = \phi + \mu \]  

(5)

where

\[ \mu = \left[ M^{-1}\hat{M} - I \right] \dot{\theta} + M^{-1} \Delta C + M^{-1} \tau_d \]  

(6)

and \( \Delta C = \hat{C} - C \). The first two terms of \( \mu \), which express the modeling error, are functions of the system states \( q \) while the last term in \( \mu \) shows the contribution of the manipulator-environment contact force to the system dynamics. The modeling errors are defined by \( \xi \) in (7).

\[ \xi = \left[ M^{-1}\hat{M} - I \right] \dot{\theta} + M^{-1} \Delta C \]  

(7)

It is assumed the modeling errors in the system are bounded such that

\[ \|M^{-1}\hat{M} - I\|_\infty \leq \alpha_{\Delta m} < \infty, \quad \forall \theta \in R^n \]  

(8)

\[ \|\Delta C\|_\infty \leq \alpha_{\Delta C} < \infty, \quad \forall \theta \in R^n. \]  

(9)

It is also assumed that the command trajectory is bounded such that \( \|q_e\|_\infty \leq \alpha_{q_e} < \infty \) and \( \|\dot{q}_e\|_\infty \leq \alpha_{\dot{q}_e} < \infty \). The lemma of Appendix B demonstrates that \( \xi \) is an \( L_\infty \)-stable function of \( q \) under the above conditions such that \( \|\xi(\cdot): L^\infty_\infty \rightarrow L^\infty_\infty \) and also there exist positive constants \( \alpha_{\xi} \) and \( \beta_{\xi} \) such that

\[ \|\xi\|_\infty \leq \alpha_{\xi} (\|q\|_\infty + \|\dot{q}\|_\infty) \]  

(10)

\[^5\] All functions based on physical systems can be safely assumed, for practical purposes, to be Lebesque measurable. Hereafter, when discussing bounds on a function, we implicitly assume that the function is Lebesque measurable.
Using the state vector \( q \), (5) may be expressed as a state differential equation

\[
\dot{q} = Aq + B[\phi + \mu]
\]

where

\[
A = \begin{bmatrix} 0 & I \\ 0 & 0 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 0 \\ I \end{bmatrix}.
\]

By considering (12) to be a linear equation where \( q \) is the output and \([\phi + \mu]\) is the input, the \( 2n \times 2n \) transfer function matrix for the system is given by

\[
D(s) = (sl - A)^{-1} B.
\]

Using the convention defined in Appendix A, the relationship in (13) may be rewritten as

\[
q = D^*(s)[\phi + \mu].
\]

The block diagram in Fig. 1 represents the dynamic behavior of the manipulator and trajectory controller.

Equation (14) is a state space differential equation written in terms of the manipulator’s position and velocity states and differs from the error equation typically employed in the stability analysis of robot trajectory controllers [19]. To analyze the tracking performance in unconstrained manipulation, (14) would typically be written in terms of the tracking error, i.e., the difference between the command trajectory and the physical trajectory. Because the interaction with the environment is directly related to the physical states and not the tracking error, (14) leads to a clearer stability analysis for trajectory control in constrained maneuvering, and, moreover, it provides a convenient basis for stability analysis when an additional feedback loop is added around the trajectory controller to tailor the system compliance.

III. ENVIRONMENT DYNAMICS AND ITS INTERACTION WITH THE MANIPULATOR

The first component of the manipulator–environment interaction is the transformation from joint space quantities to Cartesian space quantities. \( x \) is defined to be a \( 2n \times 1 \) vector representing the manipulator’s Cartesian endpoint position and velocity in the global coordinate frame. Equation (15) represents the mapping from the joint space to Cartesian space.

\[
x = \text{Kin}(q)
\]

\text{Kin}(\cdot) is comprised of the manipulator’s forward kinematics functions and Jacobian. It is assumed that \text{Kin}(\cdot) is \( L_\infty \) stable such that \( \text{Kin}(\cdot): L_\infty^{2n} \rightarrow L_\infty^{2n} \), and there exist positive constants \( \alpha_{\text{Kin}} \) and \( \beta_{\text{Kin}} \) such that

\[
\|x\| \leq \alpha_{\text{Kin}} \|q\| + \beta_{\text{Kin}}, \quad \forall q \in L_\infty^{2n}.
\]

Fig. 2. Block diagram illustrating the mapping from the system states \( q \) to the interaction force \( f \). \( f \) and \( x \) are measured relative to the same global coordinate frame.

When the manipulator comes into contact with an environment of finite stiffness, a displacement of the environment’s surface results in an interaction force. It is assumed that the environment displacement and the contact force are measured in the global coordinate frame. The relationship between the environment’s displacement and interaction force is referred to as the environment impedance. Intuitively, this impedance will be a large quantity when the environment is very “stiff” in some directions and a small quantity when the environment is very “soft” in all directions. The environment dynamics is defined as

\[
f = E(x, x_0)
\]

where \( x_0 \) is a \( 2n \) vector representing the initial position and velocity of the environment before manipulator–environment contact. \( E \) may be loosely thought of as the stiffness of the environment, though \( E \) may represent either a linear or nonlinear relationship. For situations where the manipulator can interact with the environment only in some directions, the \( E \) mapping will be singular, meaning that the component of \( f \) in the unconstrained directions is zero for all displacements \( x \). For example, in contacting a surface, the robot is constrained in the normal direction but is free to move in the two tangential directions. It is assumed that the environment is \( L_\infty \) stable such that \( E(\cdot): L_\infty^2 \times L_\infty^n \rightarrow L_\infty^n \), and there exist positive constants \( \alpha_{E1}, \alpha_{E2}, \) and \( \beta_E \) such that

\[
\|f\| \leq \alpha_{E1} \|x\| + \alpha_{E2} \|x_0\| + \beta_E, \quad \forall x \text{ and } x_0 \in L_\infty^n.
\]

The \( L_\infty \) norm of both sides of (19) is found by substituting inequality (16) into inequality (18)

\[
\|f\| \leq \alpha_{E1} \|x\| + \alpha_{E2} \|x_0\| + \alpha_{E1} \beta_{\text{Kin}} + \beta_E.
\]

Inequality (20) defines the \( L_\infty \) bound on the mapping from \( q \) to \( f \).

IV. ROBOT–ENVIRONMENT INTERACTION WITHOUT THE USE OF FORCE SENSORS

This section describes the stability of the robot manipulator and environment taken as a whole when no force sensor is used in measurement of the contact force. The block diagram of Fig. 3 is derived from (3), (6), (7), (14), (15), and (17). The linear
loop system of Fig. 3 is $L_\infty$ stable if inequality (26) is satisfied.

$$\alpha_s \alpha_t + \alpha_m \alpha_j \alpha_E_1 \alpha_{K_1} < 1.$$  

(26)

Inequality (26) is a sufficient condition for stability of the closed-loop system shown in Fig. 3. If this inequality is satisfied, the trajectory-controlled robot is guaranteed stability when interacting with a finite stiffness environment. If inequality (26) is not satisfied, no conclusions can be made. This stability criterion shows the relative contribution of the linear trajectory compensator, modeling error, manipulator dynamics, and environment dynamics to the system stability.

Furthermore, a manipulator performing unconstrained manipulation is equivalent to a manipulator interacting with an environment having zero stiffness $(\alpha_E_1 = 0)$. The trajectory control stability criterion then reduces to

$$\alpha_s \alpha_t < 1.$$  

(27)

Inequality (27) shows that, to guarantee the system stability, the system sensitivity $\alpha_t$ must decrease in inverse proportion to the modeling error $\alpha_s$. $\alpha_s$ shows the sensitivity of the system to modeling error and external forces operating on the robot and is directly related to the linear trajectory compensator. Roughly speaking, the gain $\alpha_s$ varies as the inverse of the position gain $K_p$ in the trajectory compensator; thus, the manipulator will have small sensitivity if $K_p$ is large and vice versa. $\alpha_t$ is a measurement of the nonlinear modeling error and approaches zero as the nominal model for the manipulator dynamics approaches the actual manipulator dynamics. For a system with a PD trajectory compensator and a large $\alpha_s$, the position gain $K_p$ must be large in order to provide the small sensitivity $\alpha_t$ needed to guarantee stability. Because robots, in general, perform both unconstrained and constrained maneuvers during their normal operation, inequalities (27) and (26) must both be satisfied to guarantee stability for all possible maneuvers.

In many situations, in particular in contact with a stiff environment, $\alpha_m \alpha_j \alpha_E_1 \alpha_{K_1} \gg \alpha_t$ such that the modeling error can be assumed zero. The stability condition (26) can be written as

$$\alpha_s \alpha_E_1 < \frac{1}{\alpha_m \alpha_j \alpha_{K_1}}.$$  

(28)

Inequality (28) shows that the system sensitivity must vary as the inverse of the environment stiffness to guarantee the system stability. $\alpha_m \alpha_j$ and $\alpha_{K_1}$ are measures of the manipulator’s dynamics and kinematics, respectively, and are fixed for a particular robot mechanism. $\alpha_E_1$ is a measure of the environment dynamics.

The sum within inequality (26) shows the relative contribution of the interaction loop gain and the modeling error to the system stability. In order to guarantee stability, the system sensitivity must decrease as the environment stiffness increases and vice versa. This implies that $K_p$ and $K_d$ must be small when contacting the environment.

V. ROBOT–ENVIRONMENT INTERACTION WITH FORCE FEEDBACK

We propose to modulate the contact force between the manipulator and environment by adding a compliance compensator that alters the command trajectory as a function of the measured contact force. Fig. 4 shows the block diagram of a compliance-controlled robot interacting with a finite stiffness environment. The compliance controller receives the noise-corrupted interac-
Substituting all the bounds and rearranging the terms in (33) similar to an inequality derivation of inequality (25) yields

\[
\begin{align*}
1 - \alpha_s (\alpha_l + \alpha_{M2} \alpha_j \alpha_E \alpha_{K_in} + \alpha_T \alpha_{\Delta q}) & \leq \alpha_s (\beta_l + \alpha_{M2} \alpha_j \alpha_E \beta_{K_in} \\
& + \alpha_{M2} \alpha_j \alpha_E \alpha_{x_0} + \alpha_{M2} \alpha_j \beta_l) \\
& + \alpha_s (\alpha_{M2} \alpha_j \alpha_{r_d} + \alpha_{M2} \alpha_{d_d} + \alpha_{r_d}) \\
& + \alpha_T \alpha_{\Delta q} + \alpha_T \alpha_p + \alpha_T \beta_{\Delta q}, \quad \forall t \in [0, \infty)
\end{align*}
\]

where \( \| J^-1 \| \leq \hat{\alpha} \alpha_{\Delta q} < \infty \). The right-hand side of inequality (34) has already been established as bounded quantities \( \forall t \in [0, \infty) \); therefore, the closed loop system of Fig. 4 is \( L_m \) stable if inequality (35) is satisfied.

\[
\alpha_s \alpha_l + \alpha_s \alpha_{M2} \alpha_j \alpha_E \alpha_{K_in} + \alpha_T \alpha_{\Delta q} < 1. \tag{35}
\]

Substituting \( \alpha_{\Delta q} \) from Appendix C yields

\[
\alpha_s \alpha_l + (\alpha_s \alpha_{M2} \alpha_j + \alpha_T \alpha_{\Delta q} \alpha_{H}) \alpha_E \alpha_{K_in} < 1. \tag{36}
\]

This inequality is a sufficient condition to guarantee the stability of the compliance-controlled manipulator shown in Fig. 4. If inequality (36) is satisfied, then the system shown in Fig. 4 is guaranteed to be stable; if this condition is not satisfied, no conclusion may be drawn. Note that the stability criterion in inequality (36) reduces to stability criterion of (26) if the gain of the compliance compensator \( \alpha_H \) is zero. The key difference between the two criteria is that the stability criterion contains the sum of the compliance controller gain with the gain of the system sensitivity \( \alpha_s \).

If the modeling error gain \( \alpha_s \alpha_l \) is small, then

\[
(\alpha_s \alpha_{M2} \alpha_j + \alpha_T \alpha_{\Delta q} \alpha_{H}) \alpha_E \alpha_{K_in} < 1. \tag{37}
\]

This inequality shows the relative contribution of the compliance compensator, manipulator dynamics and kinematics, trajectory compensator, and environment dynamics to the stability of the compliance-controlled robot interacting with a finite-stiffness environment. The manipulator dynamics and kinematics are fixed for a particular manipulator design; hence, \( \alpha_{M2} \alpha_j \) and \( \alpha_{K_in} \) may not be varied. For a fixed trajectory compensator, inequality (37) shows that, as the environment stiffness increases, the gain of the compliance compensator \( \alpha_H \) must decrease and vice versa. This inequality also demonstrates that stability cannot be guaranteed when the manipulator operates in the vicinity of a single point, where the maximum singular value of the inverse Jacobian \( \alpha_{r_d} \) approaches infinity. In addition, for a given environment, the impact of the trajectory compensator \( K \) on the compliance compensator \( H \) cannot be clearly assessed because both \( \alpha_s \) and \( \alpha_T \) are a function of the trajectory compensator; these conclusions can be obtained through calculation of \( \alpha_s \), \( \alpha_T \), and \( \alpha_H \) for a particular trajectory compensator and compliance compensator.

VI. STABILITY ANALYSIS FOR ROBOT INTERACTION WITH AN INFINITE STIFFNESS ENVIRONMENT

In many manufacturing situations such as robot deburring, the manipulator is likely to encounter an environment whose stiffness is much greater than that of the manipulator's mechanism or controller. In the case of a very stiff environment, the environment acts as a kinematic constraint on the robot, which means that the environment dictates the trajectory (position, velocity, etc.) of the manipulator endpoint. In this case, inequal-
(18) will not be valid because a finite environment stiffness $\alpha_{E1}$ cannot be defined. The analysis that follows does not contain the environment dynamic model $E$. Moreover, the transient period from unconstrained to constrained manipulation is ignored. This assumption implies that the manipulator experiences no impact forces during its maneuvers. Equation (1) can be rewritten as

$$f = J^{-T}[u - M\ddot{q} - C + \tau_d].$$

(38)

$\phi$ is modified to include the compliance controller $H$ of (30). Substituting the new $\phi$ in control law of (2) results in (39).

$$u = \ddot{\bar{\theta}}_D + \bar{M}\dot{\bar{q}} \star \{0 \ 0 \}^T J^{-1}H^*\{f + m\} + \bar{q}_e - q - p + \bar{C}.$$  

(39)

Substituting (39) in (38) leads to an expression for the contact force for a manipulator interacting with an infinitely stiff environment

$$f = -J^{-T}\bar{M}\bar{K} \star \{0 \ 0 \}^T J^{-1}H^*\{f\} + J^{-T}\{\bar{M}\bar{K} \star \{q_e - q - p\} + \ddot{\bar{\theta}}_D - M\ddot{\theta} + \Delta C + \tau_d\}$$

$$-J^{-T}\{\bar{M}\bar{K} \star \{0 \ 0 \}^T J^{-1}H^*\{m\}\}.$$  

(40)

The command acceleration $\ddot{\bar{\theta}}_D$, command trajectory $q_e$, states measurement noise $p$, force measurement noise $m$, and disturbance torque $\tau_d$ are all not a function of $f$. The system states $q$ and the manipulator acceleration $\ddot{\theta}$ are dictated by the environment; we denote these two quantities by $q_0$ and $\theta_0$ and also $\|q_0\|_\infty \leq \alpha_{q0} < \infty$, $\|\theta_0\|_\infty \leq \alpha_{\theta0} < \infty$. Note that $\|J^{-1}\|_\infty = \|J^{-1}\|_\infty$ and the bound on their quantities is $\alpha_{fJ}$. In a particular direction, the manipulator is either constrained by the environment or unconstrained. Along those directions which the environment constrains the manipulator, the manipulator’s position, velocity, etc. Along those directions unconstrained by the environment, the robot is performing unconstrained manipulation, and, as a direct result of the assumed stability in unconstrained maneuvers, the joint position and its derivatives are $L_\infty$-bounded quantities. Although the position and velocity may be bounded, the contact force may be unbounded.

The stability of a robot interacting with an infinitely stiff environment is determined by taking the truncated $L_\infty$ bound of both sides of (40).

$$\|f\|_{L_\infty} \leq \|J^{-T}\bar{M}\bar{K} \star \{0 \ 0 \}^T J^{-1}H^*\{f\}\|_{L_\infty}$$

$$+ \|J^{-T}\{\bar{M}\bar{K} \star \{q_e - q - p\} + \ddot{\bar{\theta}}_D - M\ddot{\theta} + \Delta C + \tau_d\}\|_{L_\infty}$$

$$+ \|J^{-T}\{\bar{M}\bar{K} \star \{0 \ 0 \}^T J^{-1}H^*\{m\}\}\|_{L_\infty},$$

$$\forall t \in [0, T].$$

(41)

Assuming $\|\bar{M}\|_\infty \leq \alpha_M < \infty$ and rearrangements of the terms of inequality (41), inequality (42) can be obtained.

$$(1 - \alpha_{fJ}\alpha_M\alpha_K\alpha_{fJ}\alpha_K)\|f\|_{L_\infty} \leq \alpha_{fJ}\alpha_M\alpha_K\alpha_{fJ}\alpha_K\|f\|_{L_\infty}$$

$$\leq \alpha_{fJ}\alpha_M\alpha_K\alpha_{fJ}\alpha_K\|f\|_{L_\infty}$$

$$+ \alpha_{fJ}\alpha_{\theta D} + \alpha_M\alpha_{\theta 0} + \alpha_{\Delta C} + \alpha_{\tau D}$$

$$+ \alpha_{fJ}\alpha_M\alpha_K\alpha_{fJ}\alpha_K\alpha_M, \quad \forall t \in [0, T].$$

(42)

The right-hand side of inequality (42) has already been established as bounded quantities $\forall t \in [0, \infty)$; therefore, the closed-loop system of Fig. 4 when the environment is infinitely stiff is $L_\infty$ stable if inequality (43) is satisfied.

$$\alpha_{fJ}\alpha_M\alpha_K\alpha_{fJ}\alpha_H < 1$$

(43)

where $\alpha_{MH}$ is the least upper bound on the maximum singular value of $M$ for all possible joint positions, $\alpha_K$ is the $L_\infty$ gain of the trajectory compensator $K$, and all other constants have the same, previously described meaning. Like the trajectory control and compliance control stability criteria, inequality (43) is a sufficient condition to guarantee the stability of the robot interacting with an infinitely stiff environment. If this inequality is satisfied, the system is guaranteed stable; if this condition is not satisfied, no conclusions may be made. Because we have ignored impact forces, this condition applies only during constrained maneuvers.

Like the previous two stability criteria, inequality (43) shows the relative contribution of the manipulator dynamics and kinematics, trajectory compensator, and compliance compensator to the system stability. This inequality shows that the gain of the compliance compensator $\alpha_K$ must vary in inverse proportion to the gain of the trajectory compensator $\alpha_K$ in order to guarantee stability. Moreover, the inequality shows that stability cannot be guaranteed when the manipulator operates near a singular point, where $\alpha_{fJ}$ approaches infinity.

**VII. EXPERIMENTAL RESULTS**

To demonstrate the stability criteria, a set of experiments was carried out on the University of Minnesota Robot. The experimental results verify inequality (43), the stability condition for a compliance-controlled robot interacting with an infinitely stiff environment.

The Minnesota Robot is a statically balanced, direct-drive, three-degree-of-freedom manipulator [10], [11]. The robot as well as the force-sensing apparatus are shown in Fig. 5. The joint position vector $q$ is equal to $[\theta_1, \theta_2, \theta_3]^T$, where $\theta_1, \theta_2,$
and $\theta_5$ are defined in Fig. 6. $\theta_i$ indicates the angular position of motor 1 or the base motor; similarly, $\theta_2$ and $\theta_3$ indicate the positions of motor 2 and motor 3, respectively. The dynamic and kinematic equations for this robot are given in [10]. The end-point position of the manipulator $x$ is given as $x = [x_1, x_2, x_3]^T$, where the reference axes are shown in Fig. 6. Reference [10] also gives the analytically derived models for manipulator dynamics $\ddot{M}$ and $\ddot{C}$, the Jacobian, and the manipulator’s kinematics $\dot{K}$. Because the Minnesota Robot is statically balanced, the gravity force is zero for all possible configurations.

The bounds $\alpha_M$ and $\alpha_H$ were computed numerically. $\ddot{M}$ and $\ddot{J}^{-1}$ are given in [10]. For any given $\theta$, the $\ddot{M}$ and $\ddot{J}^{-1}$ become constant real valued matrices. The maximum and minimum singular values of $\ddot{M}$ and $\ddot{J}^{-1}$ were computed over a finite number of positions $\theta$, evenly spaced throughout the robot workspace. $\alpha_M$ and $\alpha_H$ were taken as the maximum singular values

$$\|\ddot{M}\|_\infty \leq \alpha_M < 2.86 \text{ kg} \cdot \text{m}^2$$
$$\|\ddot{J}^{-1}\|_\infty \leq \alpha_H < 13.82 \text{ rad/m}.$$  

With the bounds on the nonlinear system dynamics established, the bounds on the linear system dynamics and the trajectory compensator can be determined. The trajectory compensator $K$ and the robot’s linear transfer function $D$ are both diagonal matrices. If we focus on the position states of the system, $D$ reduces to a $2 \times 2$ matrix of double integrators.

$$D = \frac{1}{s^2} I.$$  

(44)

Choosing $K = [K_p \ K_i] = [100 \ 10]$, the $\ddot{A}$ norms of $S$, $T$, and $K$ were analytically determined, in each case, by taking the inverse Laplace transform of the respective transfer function and applying the definition of the $\ddot{A}$ norm given in Appendix A.

$$\alpha_s = \| [I + DK] \|^{-1} D \|_\ddot{A} = \frac{1}{K_p}$$
$$\alpha_T = \| [I + DK] \|^{-1} DK \|_\ddot{A} = 1.0$$
$$\alpha_K = \| K \|_\ddot{A} = K_p.$$  

To verify that inequality (43) guarantees the stability of a compliance-controlled robot interacting with an infinitely stiff environment, a series of tests was performed in which the Minnesota Robot contacted a reinforced aluminum wall, an effectively infinitely stiff environment. To simplify the tests, motor 2 was locked so that the motion of the robot endpoint was within the horizontal ($x_3 = 0$) plane. A three-dimensional piezoelectric force sensor was mounted at the robot endpoint, and numerical transformations were performed by the control computer to resolve endpoint forces into the global Cartesian coordinate frame.

Because motion was confined to the horizontal plane, $H(s)$ was a $2 \times 2$ matrix operating on the global, $x_1$, $x_2$, contact forces. In all experiments, the compliance compensator $H$ was chosen to supplement compliance in the normal or $x_3$ direction.

$$H = \begin{bmatrix} 0 & 0 \\ 0 & \frac{H_0}{(s/\omega) + 1} \end{bmatrix}.$$  

(45)

$H$ was also implemented digitally using the matched pole-zero method. The sampling time was 7.97 ms. $\omega$ was empirically chosen to filter high-frequency noise from the force signal and was fixed as 20 rad/s throughout all experiments. By taking the $\ddot{A}$ of $H$, $\alpha_H = H_0$, inequality (43) can be rearranged as

$$H_0 < \frac{1}{\alpha_T \alpha_M K_p} = 1.98 \times 10^{-5} \text{ m/N}.$$  

(46)

This inequality guarantees that manipulator stability if the gain $H_0$ of the compliance compensator is less than $1.98 \times 10^{-5}$ m/N. If the $H_0$ is set higher than this constant, no conclusions based on (46) can be made.

In the first series of experiments, the robot was commanded to move along a straight-line Cartesian trajectory intersecting a wall surface (Fig. 7). Throughout the maneuver, the robot approximately followed the command trajectory in the $x_1$ direction (Fig. 8). As shown in Fig. 9, the robot followed the commanded $x_2$ trajectory during the unconstrained portion of the maneuver and followed the wall after a brief rebound.

In the first experiment of this series, $H_0$ was chosen to be $1.9 \times 10^{-3}$ m/N, satisfying the stability condition in inequality (46). Fig. 10 shows that the system is stable when interacting with the wall. In another set of experiments, $H_0$ was set to $5.0 \times 10^{-4}$ m/N. The results are shown in Fig. 11. They verified that the compliance compensator violates the stability.
Fig. 7. Graph of command and actual trajectory of the robot endpoint in the $x_1$-$x_2$ plane. The command trajectory intersects the wall’s surface. The robot approximately follows the command trajectory during the unconstrained portion of the movement. After the initial contact, the manipulator rebounds from the wall due to the impact force. The robot follows the wall surface once contact is restored.

Fig. 8. Motion in the unconstrained direction as a function of time. The actual motion in the $x_1$ direction approximately follows the commanded motion.

Fig. 9. Motion in the constrained direction as a function of time. The actual motion approximately follows the commanded motion until contact occurs at $t = 1.3$ s; therefore, motion in the $x_2$ direction is constrained by the wall.

criterion when unstable contact, as indicated by the unbounded contact force, occurs. Finally, the third experiment (Fig. 12), where $H_0$ was set to $1.0 \times 10^{-4}$ m/N, violated the stability criterion; yet the system was stable. This experiment illustrated that failure to satisfy the stability criterion does not imply that the system will be unstable and, moreover, showed that inequality (43) defines a conservative stability bound for the compliance compensator $H$.

VIII. SUMMARY AND CONCLUSIONS

We have derived three stability conditions: two criteria guarantee stability when a robot interacts with a finite-stiffness environment, and the third criterion guarantees stability when a compliance-controlled robot interacts with an infinite-stiffness environment. The first criterion establishes a condition for the stability of a robot and environment when force is not measured for feedback. The first criterion [see (26)] may be simplified to guarantee manipulator stability in unconstrained maneuvers by assuming the environment stiffness is zero. It is shown that the position gain of a PD trajectory compensator must increase in proportion to the environment’s stiffness; interaction with a stiffer environment requires a larger position gain to guarantee stability than with a less stiff environment. The second stability criterion represents a stability condition when force feedback has been used to modulate the contact forces. In order to guarantee stability for a given trajectory compensator, the gain of the force compensator $H$ must decrease as the environment’s stiffness increases and must be zero if the manipulator operates in the vicinity of a singular point.
A set of experiments was performed to verify the criterion guaranteeing the stability of a manipulator interacting with an infinite stiffness environment [see inequality (43)]. All impact forces were eliminated by commanding the manipulator to move along a path located behind a reinforced aluminum wall. These tests confirmed the assumptions of the stability criterion and demonstrated the sufficiency of the condition. The compensator satisfying the criterion produced stable manipulation, and the compensator that produced unstable manipulation did not.

**APPENDIX A**

**MATHEMATICAL CONVENTIONS**

1) The $L_{\infty}$ norm of an $n \times 1$ vector function $f(t)$ is defined as [20]

$$\|f\|_\infty = \sup_{t \geq 0} \|f(t)\|$$

(A1)

where $\|f(t)\|$ denotes the Euclidean norm. If $\|f\|_\infty \leq \infty$, then we say that $f \in L^n_{\infty}$. For functions that may grow unboundedly, a truncated $L_{\infty}$ norm is defined as

$$\|f\|_{\infty} = \sup_{t \geq 0} \|f(t)\|, \quad t \geq 0 \text{ and } t < T. \quad (A2)$$

2) $H$ is a $L_{\infty}$ stable operator if

I) $g = H(f) \in L^n_{\infty}$ whenever $f \in L^n_{\infty}$

and

II) $\|g\|_\infty = \|H(f)\|_\infty \leq \gamma \|f\|_\infty + \beta \quad (A3)$

where $\gamma$ denotes the $L_{\infty}$ norm of $H$ and, loosely speaking, represents the "gain" of $H$ [20]. Note that the symbolism $H(\cdot) : L^n_{\infty} \rightarrow L^n_{\infty}$ may be interpreted as "the function $H$ maps a bounded input $f$ to a bounded output $g$.

3) If $H$ is a linear operator, then the output $g(t)$, will be equal to the convolution of $h(t)$, the impulse response of $H(z)$, and $f(t)$. For brevity, we use the following shorthand convention throughout the paper for convolution:

$$g(t) = H^*(f).$$

(A4)

The $L_{\infty}$ gain of $H$ is characterized by the $L_{\infty}$ norm, which is defined as [20]

$$\|H\|_A = \sup_{\|f\|_\infty \neq 0} \|H^*f\|_\infty, \quad f \neq 0 \quad (A5)$$

where $f$ is an input vector. The following property of the $A$ norm is true [20]:

$$\|H^*f\|_\infty \leq \|H\|_A \|f\|_\infty, \quad f \in L^n_{\infty}. \quad (A6)$$

The $A$ norm is computed as follows. Assuming $H(s)$ is strictly proper, the impulse response of $H(s)$ is the inverse Laplace transform matrix $h(t)$ whose elements are scalar functions of time. If all eigenvalues of $H(s)$ have negative real components, the norm $\|H\|_A$ is defined by [20]

$$\|H\|_A = \int_0^\infty \|h(t)\| \, dt. \quad (A7)$$

For a scalar system, $h(t)$ is a scalar function and the above equation reduces to

$$\|H\|_A = \|h(t)\|_1 = \int_0^\infty |f| \, dt. \quad (A8)$$

4) The induced matrix norm is given by

$$\|A\|_\infty = \max_i \sum_{j=1}^n |a_{ij}| \quad (A9)$$

where $a_{ij}$'s are the matrix members.

**APPENDIX B**

**Lemma:** Under the given conditions, $\xi$ is $L_{\infty}$ stable. The truncated $L_{\infty}$ norm of both sides of (7) is given by

$$\|\xi\|_{T_\omega} \leq \alpha_{M1} \|\phi\|_{T_\omega} + \alpha_{M2} \|\Delta C\|_{T_\omega}, \quad \forall t \in [0, T] \quad (B1)$$

where $\alpha_{M1}$ is defined in (8) and $\alpha_{M2}$ is defined after inequality (23). Substituting for $\|\phi\|_{T_\omega}$ from inequality (4) into (B1) results in

$$\|\xi\|_{T_\omega} \leq \alpha_{M1} \|\Delta K\|_{T_\omega} + \alpha_{M2} \|\Delta C\|_{T_\omega}. \quad (B2)$$

Substituting for $\|\phi\|_{T_\omega}$, $\|q_e\|_{T_\omega}$, $\|p\|_{T_\omega}$ and $\|\Delta C\|_{T_\omega}$ into (B2) results in

$$\|\xi\|_{T_\omega} \leq \alpha_{K} \|q\|_{T_\omega} + \beta, \quad \forall t \in [0, T] \quad (B3)$$

where $\alpha_{K} = \alpha_{M1} \alpha_{K}$ and $\beta = \alpha_{M2} \alpha_{K} \alpha_{p} + \alpha_{M1} \alpha_{K} \alpha_{p}$. Inequality (B3) shows that $\xi(t)$ is bounded over $[0, T]$. Because this reasoning is valid for every finite $T$, it follows that $\xi \in L^n_{\infty}$ if $g \in L^n_{\infty}$. Suppose $q \in L^n_{\infty}$; then, by using the same reasoning as before

$$\|\xi\|_\infty \leq \alpha_{K} \|q\|_\infty + \beta, \quad \forall t \in [0, \infty]. \quad (B4)$$

The right-hand side of inequality (B4) is independent of $T$, and, therefore, inequality (B4) demonstrates the $L_{\infty}$ stability of the mapping $\xi$.

**APPENDIX C**

**Lemma:** Under the given conditions, $\Delta q$ is $L_{\infty}$ stable. The truncated $L_{\infty}$ norm of both sides of (30) is given by

$$\|\Delta q\|_{T_\omega} \leq \alpha_{J1} \|J\|_{T_\omega} + \|m\|_{T_\omega}, \quad \forall t \in [0, T] \quad (C1)$$

where $\alpha_{J1} \cong \|H\|_J$ and $\alpha_{J1} \cong \|J^{-1}\|_\infty < \infty$. Substituting inequality (20) into (C1) results in

$$\|\Delta q\|_{T_\omega} \leq \alpha_{J1} \|q\|_\infty + \beta, \quad \forall t \in [0, T] \quad (C2)$$

where $\alpha_{J1} = \alpha_{J1} \alpha_{J1} \alpha_{K1}$ and $\beta = \alpha_{J1} \alpha_{J1} \alpha_{K1} \alpha_{p} + \alpha_{J1} \alpha_{K1} \alpha_{p}$. The remainder of the proof is similar to the proof in Appendix B; therefore,

$$\|\Delta q\|_\infty \leq \alpha_{J1} \|q\|_\infty + \beta, \quad \forall t \in [0, \infty]. \quad (C2)$$
